ABSTRACT

Approximately 65% of Iowa's roads are surfaced with aggregates composed of crushed limestone and/or gravel. Rural Iowan's regard these roads as a very important part of their lives. Therefore, the slide-tape presentation, "Maintaining Granular Surfaced Roads" was developed to aid the motor grader operator to better understand the procedures required to maintain aggregate surfaced roads.

A typical cross-section is presented with the proper nomenclature assigned to the roadway features to facilitate the operator's understanding of the basic terms used throughout the program. The following areas are expanded: safety, dragging, cutting, intersections, superelevations, and reporting any discrepancies.

The operator's attention to detail can enhance the economy of the state and contribute to the savings of lives on rural highways.
MAINTAINING GRANULAR SURFACED ROADS

9. Title—"Maintaining Granular Surfaced Roads"

* Rural Iowans living along secondary roads regard those roads as a very important part of their lives. These highways provide a means of transporting their commodities to market, their children to school, mail to their homes, and act as links to metropolitan shopping centers.

Many rural Iowans still remember when the poll tax could be worked off by three days labor on the roads bordering their farms. Even today, the people assigned to maintain the county systems find that people in their district take a very personal interest in the roads, and don't hesitate to point out areas that are improperly maintained.
This presentation was developed to aid the motor grader operator in maintaining granular surfaced roads. The presentation is a guide and is not intended as a standard specification or regulation. Most of the information presented can be found in the Blading Aggregate Surfaces manual available through the National Association of County Engineers.

Over 69,000 miles of Iowa's highways are surfaced with aggregates composed of a mixture of coarse and fine particles. Approximately 65 percent of the roads are surfaced with crushed limestone from quarries.

Another 35 percent is surfaced with natural sands or gravel, which are found in river beds or as natural deposits along old stream beds.

Different sizes of aggregates are blended to provide the qualities needed to pack and interlock the particles.

The largest aggregate is ordinarily not more than one inch in diameter.
Particles smaller than sand, called fines, are used with the larger aggregates and act as a cement when moisture is present to bind the aggregates together.

County roads, as seen in this cross-section, have a raised centerline which is referred to as the crown. Retaining the crown is very important and is maintained by correct motor grader operation.

Also note that the shoulders maintain continuity with the road surface before breaking sharply at the foreslopes.

Correct motor grader operation maintains the crown and shoulder profile, and provides correct elevations and drainage which make the road safe for motor vehicle movement at speeds up to 55 MPH.

Grader operators maintain smooth aggregate roadbeds through an action referred to as dragging.

This is preferably done when the aggregate and fines are moist in order to provide a lasting binding action.
The dragging and rolling action created by the grader's moldboard helps to remix the fines and aggregates and respreads them across the road's surface. *

The grader's speed depends on the type of grader, the angle of the blade and the road's condition. Too much speed will make the blade bounce. This causes alternate high and low areas which are commonly referred to as washboarding. A safe speed is about 3 miles per hour in 2nd gear. *

Because the grader operator is constantly exposed to traffic, the grader is furnished with safety equipment which must be checked on a daily basis. *

The flags on the ends of the moldboard must be in place and in good condition. *

Check the reflective "slow moving vehicle" emblem to make sure it is in place and clean. *

All lights including the headlights, brake lights and turn signals should be checked, cleaned, and bulbs should be replaced if necessary. *
The rotating beacon or flashing light on the cab should also be clean and operational. *

If visibility is cut to a dangerous level by fog, rain or snow, the operator should not take the grader on the road. *

The next several steps will help you set up and adjust your grader so you can produce a smooth surface. *

Before starting, check the condition of the grader blade for gouges and wear. If necessary, take the worn sections from the middle and invert them so they are now at the outside of the blade. *

A double thickness of blade can also be placed across the center to increase the blade's life. In either case, when the blade is heavily worn, you will need to install new blades. *

Next, place the moldboard so the outer end is at the edge of the road's surface and next to the shoulder line. *

Tilt the moldboard forward to get a dragging action rather than a cutting action. *
Then adjust the angle of the moldboard between 30 and 45 degrees. *

In most cases you should tilt or lean the front wheels slightly 10 to 15 degrees towards the direction you want the aggregate to roll. *

Occasionally blade the road surface against the flow of traffic. This eliminates drifting of the aggregate onto the ends of bridges, intersections and railroad crossings. *

And finally, when necessary, don't hesitate to stop and repair holes, rutted areas and poor surface drainage conditions with your shovel. *

As you have seen, aggregate-surfaced roads are graded higher in the middle than the sides to form a crown. * The crown allows water to flow into the ditch. *

Roads with poor crowns trap water, causing the crust to become saturated and break up, eventually producing * potholes, washboards and a poor riding surface. *
The degree of crown is the amount of slope from the middle of the road toward the shoulder. Good drainage requires a crown of 1/2 to 3/4 inch for each foot of width, measured from the center of the roadway to the outside edge. *

There are several things to keep in mind when setting up your machine to obtain the proper crown. *

The best way to measure crown is to use the "crown gauge", commonly called a slope meter, which is mounted on the motor grader. *

Use your slope meter to set your blade to the correct amount of slope by raising the end of the blade nearest the center of the road so it is higher than the blade at the outside edge of the road. *

Do NOT cut a groove at the outer edge of the road surface. If a groove is made, a secondary ditch will be formed preventing proper drainage of the road surface. *
Correct grading will promote the formation of a crust. When properly blended, aggregates and fines will dry to form a hard crust that provides a smooth wearing surface. * This crust will carry traffic until that crust breaks down. It also functions to keep the base stable by shedding water. *

When grading, the operator must not break this crust, but only smooth the surface and drag excess material across the road. *

PAUSE FOR SLIDE 5 SEC. *

But eventually, traffic and climatic conditions will completely break down the crust and the road will again need reshaping. *

Shoulders require maintenance procedures similar to those which apply to the roadbed. *

The shoulder must be shaped to allow water to drain to the foreslope. Therefore, the slope of the shoulder must be equal to or greater than the road surface. *
Follow these steps for shoulder blading. Adjust the blade so the inside edge of the shoulder is at the same elevation as the outside edge of the road surface. This will allow the water to drain and eliminate the possibility of secondary ditches.*

Blade the shoulders as needed to recover loose aggregate and valuable fines. At the same time, you will destroy unwanted vegetation in these areas.*

Spread the loose fines and aggregate on the road surface to help build the crown and stabilize the surface aggregate.*

During long periods of dry weather, blading is done to remove excess loose aggregate.*

You can store this aggregate in windrows along the shoulder.*

However, when adequate rainfall returns, these windrows should be spread back across the road's surface again.*
Still, windrows should be kept to a minimum to reduce the possibility of cars hitting them and causing the drivers to lose control of the vehicle. *

During periods of moisture caused by heavy rain or melting snow, reshaping of the road surface may be required. *

Just like the good old days, under these conditions, traffic tends to scatter the aggregate, flatten the crown, * make deep ruts in the road and create rough surfaces similar to * washboarding. These conditions cannot be corrected by smoothing the surface. Reshaping is required. *

Reshaping involves mixing the aggregate base to get the correct blend of fines and different size aggregates. This BLENDED material is then bladed into a properly crowned road surface. *

Check with the foreman to see if more aggregate or fines need to be added to the surface, particularly in rough spots, thin or washed out areas. This is called remixing. *
Remixing is largely learned by experience and correct mixing depends on the materials at hand. * The following steps will provide you with a foundation of knowledge from which to work. *

Tilt the moldboard UPRIGHT so it is in the CUTTING position. *

Adjust the moldboard to a 30 to 45 degree angle to produce a moving and rolling action of the mixed aggregate toward the center of the road. *

Lean the front wheels at a 10 to 15 degree angle from vertical in the direction the aggregate will roll across the blade. *

Put enough pressure on the blade to cut washboard ridges. *

When necessary, due to potholes or washboarding, scarify 2 to 4 inches deep. This should be done only when the aggregate is moist so it will quickly compact again. *

Watch the blade action and adjust as necessary to assure correct cutting and mixing. *
Check to see if more passes are needed for remixing, or to cut to the bottom of potholes and washboards, or to windrow more aggregate to the center of the road.*

When cutting is completed, spread the aggregate back over the road.* Be sure to blade the material into the proper crown.*

Special techniques are used at road intersections. At the intersection of two aggregate surfaced roads, you must gradually eliminate the crown on each road,* starting approximately 50 to 100 feet before the intersection.*

Check to see if another pass or two is needed to eliminate the crown.*

However, the crown will be retained on "through roads" which are intersected by county roads having stop signs.*

The shoulders should still slope in the usual fashion. Do not allow excessive superelevations to develop in the radii of intersections.*
At the intersection of aggregate surfaced roads and paved roads, the crown of the aggregate road is gradually eliminated 50 to 100 feet in front of the intersection. *

Do not allow loose aggregate to remain on the paved road. When traffic permits, pull onto the pavement, * drop the blade, put the machine into reverse and pull the loose aggregate back onto the aggregate road. *

Because traffic safety procedures must be carefully observed at intersections, the operator may wish to blade PARALLEL to the pavement edge * or even clean it with a shovel or broom. *

Where aggregate roads cross railroads, the operator must assure that the road adjacent to the tracks is cleaned. * Once again lower the blade and pull the excess aggregate away from the tracks. *
Driveways also require special consideration. The driveway should meet the roadway at the shoulder line.

PAUSE 5 SEC. *

Make sure you do not grade a hump into the road where it meets the driveway. *

To grade a driveway properly, the moldboard should be adjusted to insure that the elevation of the road and the driveway are on the same plane at the shoulder line. *

Where possible, correct the grade of the driveway so there is no difference in grade where it connects with the road. *

The crown of the driveway must be eliminated at its junction with the edge of the road or there will be a hump. *

Bridges also require special consideration, depending on the bridge type. Most wooden bridges do not have a crown; however, most others, particularly concrete bridges, do in order to provide drainage. *
First check to see if the bridge is designed for aggregate cover; if there is a question, ask the County Engineer. *

Gradually shape the crown of the approach 50 to 100 feet from the bridge to fit the floor. Several passes may have to be made to insure * that an abrupt depression does not develop at the bridge ends. *

Don't let aggregate build up at the ends of a bridge. Drop your blade, * put the grader in reverse, and pull off the excess aggregate. *

Hilltops also require special care. As the front and then the rear wheels pass over the hilltop, you must gradually adjust the blade up, then back down again. * Otherwise, you will cut the crest off the top of the hill, as illustrated here.

PAUSE 5 SEC. *

When going down hill, shift into a lower gear. This will tend to reduce washboarding due to a bouncing blade action caused by too much speed. *
Do not use the blade as a brake on hills. Increased blade pressure will cause you to cut the grade steeper and also cause an accumulation of excess aggregate at the bottom of the hill.  

Therefore, when grading valleys, retain the blade in normal position as the front wheels pass over the valley bottom; then gradually lower the blade as it passes over the lowest elevation and gradually raise it again as the rear wheels pass over the bottom of the valley.  

At curves, superelevations must be retained to prevent vehicles from sliding off the road due to centrifugal force.  

Superelevation is where the outside edge of the road surface is higher than the inside edge. The tighter the curve, the more superelevation will be needed.
Grading from a non-elevated area with a crown into a superelevated curve without a crown, and into a crowned area again, should be done gradually. Begin to eliminate the crown 50 to 100 feet from the curve.*

At curves, shoulders are to be sloped downward from the superelevated part of the road's edge to the foreslopes.*

At district meetings, or even while blading, the conscientious operator must inform the foreman about certain conditions that need attention.*

Typical situations may include damaged culverts and pipes, ditches that no longer drain, broken reflectors, signs that need replacing or moving,* or areas with high degrees of erosion.

In addition, all complaints of people living in the district should be reported to the foreman for consideration.*
As you have seen, a proficient and responsible operator has an important job. The operator's attention to detail can enhance the economy of the State and contribute to the saving of lives through safe secondary road systems.
